1. INTRODUCTION

This project concerns the design and analysis of algorithms to be run in a processor-rich environment. We focus primarily on algorithms that require no global control and that can be run on systems with only local connections among processors. We investigate the properties of these algorithms both theoretically and experimentally. The experimental work has been done on the ZMOB, a parallel computer operated by the Laboratory for Parallel Computation of the Computer Science Department at the University of Maryland, although recently we have gained access to a BBN Butterfly computer as well.

The ZMOB consists of 128 processors which communicate by message passing over a communications network which provides a complete network of connections between processors. The start-up time for interprocessor communication, the per-word transmission overhead, and the floating point computation time is all of the same order of magnitude.

It is important to be precise about how we use the ZMOB in our research. What we do not do is to investigate algorithms for the ZMOB itself. Instead we use the fact that the ZMOB appears to be a completely connected network to simulate various locally connected networks of processors. Thus we can investigate, in a realistic setting, the effects on our algorithms of various processor interconnections.

Our activities may be divided into four categories: algorithms, software development, theoretical analysis, and experimental analysis.

To give our work direction, we have focused on dense and sparse problems from numerical linear algebra. We discuss in this summary the research projects that we have pursued under this grant support over the past year.

2. Summary of Work

Our activities have ranged from theoretical analysis to algorithmic design and software development. We summarize this work in the following sections. For details, consult the annotated list of references in Appendix A.

2.1 Data-Flow Algorithms and Domino

We have based most of our work in this area on the notion of a data-flow algorithm. The computations in a data-flow algorithm are done by independent computational nodes, which cycle between requesting data from certain nodes, computing, and sending data to certain other nodes. More precisely, the nodes lie at the vertices of a directed graph whose arcs represent lines of communication. Each time a node sends data to another node, the data is placed in a queue on the arc between the two nodes. When a node has requested data from other nodes, it is blocked from further execution until the data it has requested arrives at the appropriate input queues. An algorithm organized in this manner is called a data-flow algorithm because the times at which nodes can compute is controlled by the flow of data between nodes.

Data-flow algorithms are well suited for implementation on networks of processors which communicate by message passing. Each node in a computational network is regarded as a process residing on a fixed member of a network of processors. We allow more than one node on a processor. Since many nodes will be performing essentially the same functions, we allow nodes which share a processor also to share pieces of reentrant code, which we call node programs. Each processor has a resident node communication and control system to receive and transmit messages from other processors and to awaken nodes when their data has arrived.

Data-flow algorithms have a number of advantages.

THE PARTY OF THE P

- 1. The approach eliminates the need for global synchronization.
- 2. Parallel matrix algorithms, including all algorithms for systolic arrays, have data-flow implementations.
- 3. Data-flow algorithms can be coded in a high-level sequential programming language, augmented by two communication primitives for sending and receiving data.
- 4. Data-flow computations can be supported by a very simple node communication and control system.
- 5. The approach allows the graceful handling of missized problems, since several nodes can be mapped onto one processor.
- 6. By mapping all nodes in a data-flow algorithm onto a single processor, one can debug parallel algorithms on an ordinary sequential processor.

Because of the conceptual convenience and practical utility of the data-flow approach, and because of the absence of any standard for writing transportable

algorithms for parallel machines, we have implemented these ideas in a node communication and control system called Domino. We have documented the system and provided examples of its use in a technical report. The system currently runs on the ZMOB, Vaxes under Unix or VMS, Sun workstations, and IBM PC's. A Butterfly implementation is underway. The code is currently being used for numerical analysis and for neural network studies at Maryland. The system has been very valuable to us in our research, and will be used in a course on parallel computation taught next fall at Maryland. We have already received numerous inquiries from potential users in industry and academics and will make Domino available over the Arpanet through Netlib at Argonne National Lab.

2.2 Theoretical Developments

Work has been done in the design of parallel architectures and in the analysis of parallel algorithms.

Our work on the determinacy of our data-flow model for parallel computation led us to propose a modification of the design of systolic arrays in order to eliminate the need for global synchronization. Each cell in the array is augmented by a feedback circuit so that data is sent from one cell to another only when the receiver is ready to process it. We call such networks systaltic arrays.

David C. Fisher completed a thesis partially supported by this grant which studies the complexity of various tasks in matrix computation, assuming that processors perform computations so fast that the communication delay in sending between physically distant processors is significant. Lower bounds on execution time were obtained, and optimal algorithms were derived for several problems.

2.3 Algorithm Design, Analysis, and Testing

The chief difficulty with the data-flow approach is that the behavior of the algorithms cannot be analyzed purely from the local viewpoint of the node programs. This is one reason for supplementing theory with experiment.

This year, we devised a number of new parallel algorithms. For dense matrices we developed algorithms for computing the QR factorization of a matrix and a parallel version of the QR algorithm for computing eigenvalues. For sparse matrices, we are working on simultaneous iteration methods for eigenvalues and block conjugate gradient algorithms for solving linear systems.

3. Summary

Four papers supported under this grant appeared in refereed journals during this year, and two were accepted for publication. Invited talks were given at universities and at conferences whose themes ranged from parallel processing to statistics and mathematical programming. One graduate student completed his dissertation and two others made substantial progress. The Domino software has been documented and prepared for distribution.

Our work resulted in a collection of parallel algorithms for matrix computations, a data-flow operating system to support experiments, and theoretical investigation into complexity and determinacy issues in parallel matrix computations.

I. Technical Reports

(1) G. W. Stewart, Computing the CS Decomposition of a Partitioned Orthonormal Matrix, TR-1159, May, 1982.

This paper describes an algorithm for simultaneously diagonalizing by orthogonal transformation the blocks of a partitioned matrix having orthonormal columns.

(2) G. W. Stewart A Note on Complex Division, TR-1206, August, 1982.

An algorithm (Smith, 1962) for computing the quotient of two complex numbers is modified to make it more robust in the presence of underflows.

(3) D. P. O'Leary, Solving Sparse Matrix Problems on Parallel Computers, TR-1234, December, 1982.

This paper has a dual character. The first part is a survey of some issues and ideas for sparse matrix computation on parallel processing machines. In the second part, some new results are presented concerning efficient parallel iterative algorithms for solving mesh problems which arise in network problems, image processing, and discretization of partial differential equations.

(4) G. W. Stewart, A Jacobi-like Algorithm for Computing the Schur Decomposition of a Non-Hermitian Matrix, TR-1321, August, 1983.

This paper describes an iterative method for reducing a general matrix to upper triangular form by unitary similarity transformations. The method is similar to Jacobi's method for the symmetric eigenvalue problem in that it uses plane rotations to annihilate off-diagonal elements, and when the matrix is Hermitian it reduces to a variant of Jacobi's method. Although the method cannot compete with the QR algorithm in serial implementation, it admits of a parallel implementation in which a double sweep of the matrix can be done in time proportional to the order of the matrix.

(5) D. P. O'Leary and G. W. Stewart, Data-Flow Algorithms for Matrix Computations, TR-1366, January, 1984.

In this work we develop some algorithms and tools for solving matrix problems on parallel processing computers. Operations are synchronized through data-flow alone, which makes global synchronization unnecessary and enables the algorithms to be implemented on machines with very simple operating systems and communications protocols. As examples, we present algorithms that form the main modules for solving Liaponuv matrix equations. We compare this approach to wavefront array processors and systolic arrays, and note its advantages in handling missized problems, in evaluating variations of algorithms or architectures, in moving algorithms from system to system, and in debugging parallel

algorithms on sequential machines.

(6) G. W. Stewart, W. F. Stewart D. F. McAlister, A Two Stage Iteration for Solving Nearly Uncoupled Markov Chains, TR-1384, 1984.

This paper presents and analyses a parallizable algorithm for solving Markov chains that arise in queuing models of loosely coupled systems.

(7) Dianne P. O'Leary and Robert E. White, Multi-Splittings of Matrices and Parallel Solution of Linear Systems, TR-1362, December, 1983.

We present two classes of matrix splittings and give applications to the parallel iterative solution of systems of linear equations. These splittings generalize regular splittings and P-regular splittings, resulting in algorithms which can be implemented efficiently on parallel computing systems. Convergence is established, rate of convergence is discussed, and numerical examples are given.

(8) David C. Fisher, In Three-Dimensional Space, the Time Required to Add N Numbers is $O(N^{1/4})$, TR-1431, August, 1984.

How quickly can the sum of N numbers be computed with sufficiently many processors? The traditional answer is $t = O(\log N)$. However, if the processors are in R^d (usually $d \le 3$), addition time and processor volume are bounded away from zero, and transmission speed and processor length are bounded, $t \ge O(N^{1/d+1})$.

(9) Dianne P. O'Leary, G. W. Stewart, On the Determinacy of a Model for Parallel Computation, TR-1456, November, 1984. (Obsolete: see TR-1553)

In this note we extend a model of Karp and Miller for parallel computation. We show that the model is deterministic, in the sense under different scheduling regimes each process in the computation consumes the same input and generates the same output. Moreover, if the computation halts, the final state is independent of scheduling.

(10) Dianne P. O'Leary, Systolic Arrays for Matrix Transpose and Other Reorderings, TR-1481, March, 1985.

In this note, a systolic array is described for computing the transpose of an $n \times n$ matrix in time 3n-1 using n^2 switching processors and n^2 bit buffers. A one-dimensional implementation is also described. Arrays are also given to take a matrix in by rows and put it out by diagonals, and vice versa.

(11) Dianne P. O'Leary, G. W. Stewart, Assignment and Scheduling in Parallel Matrix Factorization, TR-1486, April, 1985.

We consider in this paper the problem of factoring a dense $n \times n$ matrix on a network consisting of P MIMD processors when the network is smaller than the number of elements in the matrix $(P < n^2)$. The specific example analyzed is a computational network

that arises in computing the LU, QR, or Cholesky factorizations. We prove that if the nodes of the network are evenly distributed among processors and if computations are scheduled by a round-robin or a least-recently-executed scheduling algorithm, then optimal order of speed-up is achieved. However, such speed-up is not necessarily achieved for other scheduling algorithms or if the computation for the nodes is inappropriately split across processors, and we give examples of these phenomena. Lower bounds on execution time for the algorithm are established

(12) Dianne P. O'Leary, G. W. Stewart, From Determinacy to Systaltic Arrays, TR-1553, August, 1985.

In this paper we extend a model of Karp and Miller for parallel computation. We show that the extended model is deterministic, in the sense that under different scheduling regimes each process in the computation consumes the same input and generates the same output. Moreover, if the computation halts, the final state is independent of scheduling. The model is applied to the generation of precedence graphs, from which lower time bounds may be deduced, and to the synchronization of systolic arrays by local rather than global control.

(13) David C. Fisher, Matrix Computation on Processors in One, Two, and Three Dimensions, TR-1556, August, 1985.

HAVE THE TAXABLE PARTY OF THE P

Suppose a problem is to be solved on a d-dimensional parallel processing machine. Assume that transmission speed is finite. Under this and other "real world" assumptions, if a problem requires I inputs, K outputs and T computations, then time required to solve the problem is greater than or equal to $O((\max(I^{1/d}, K^{1/d}, T^{1/(d+1)})))$. Algorithms for certain matrix computations are developed. The problems are divided into atoms. The algorithms are described and analyzed with the use of step and processor assignment f unctions. These assign each atom to a step and a processor. Here is a table showing the time for algorithms presented in this paper:

Problem	Linear Grid (1-D)	Square Grid (2-D)	Cubic Grid (3-D)
Summation of k numbers	O(k)	$O(k^{1/2})$	$O(k^{1/3})$
Multiply a $k \times k$ matrix by a k vector	$O(k^2)$	O(k)	$O(k^{2/3})$
Multiply two $k \times k$ matrices	$O(k^2)$	O(k)	$O(k^{3/4})$
Cholesky factorization of a $k \times k$ matrix		O(k)	

Except for matrix multiplication in 3-dimensions, these times are a constant multiple of the lower bounds. Programs are given which will execute these algorithms on an appropriate parallel processing machine.

(14) D. P. O'Leary, G. W. Stewart, R. van de Geijn, DOMINO: a message passing environment for parallel computation. TR-1648, April, 1986.

This report is a description of DOMINO, a system to coordinate computations on a network of processors. It implements an extension of a model of parallel computation (Karp and Miller, SIAM J. Appl. Math., 1966), in which computations are synchronized by messages passed between the processes performing the computations. The system is organized in such a way that meaningful debugging can be done on a single processor. In order to make DOMINO transportable, system dependent features have been isolated in two

interfaces.

(15) G. W. Stewart, Communication in parallel algorithms: an example, April, 1986.

The purpose of this note is to describe and analyze a parallel algorithm for computing the QR factorization of an $n \times p$ matrix. The algorithm is designed to run on a ring of r processors that communicate by message passing.
